

two step mantoux test

two step mantoux test is a diagnostic procedure used primarily to detect latent tuberculosis infection, particularly in individuals who require serial testing such as healthcare workers. This test involves administering two separate tuberculin skin tests (TST) spaced one to three weeks apart to enhance the accuracy of diagnosis. What is the Two Step Mantoux Test?

The two step Mantoux test is a diagnostic technique used to detect latent tuberculosis infection by administering the tuberculin skin test twice within a short interval. The Mantoux test itself involves injecting a purified protein derivative (PPD) of the tuberculosis bacterium intradermally and measuring the skin's induration response 48 to 72 hours later. The two step approach is designed to identify individuals with a waned immune response to TB antigens, which may not react strongly on the initial test but show a boosted response in the second test.

Definition and Background

The Mantoux test was developed over a century ago and remains a cornerstone

in tuberculosis screening. The two step method was introduced to improve sensitivity and reduce the likelihood of misclassifying individuals who have been previously exposed to TB or vaccinated with Bacillus Calmette-Guérin (BCG). It is especially important in populations undergoing periodic screening, such as healthcare personnel, to distinguish between new infections and boosted immune memory.

Purpose and Clinical Importance

The primary purpose of the two step Mantoux test is to enhance the detection of latent tuberculosis infection and to reduce false-negative results caused by a waning immune response. This is critical in public health efforts to control tuberculosis transmission, especially in high-risk groups.

Importance in Healthcare Settings

Healthcare workers are frequently tested for TB infection due to their increased exposure risk. The two step Mantoux test helps identify latent infections accurately before they progress to active tuberculosis, enabling timely intervention and treatment.

Prevention of Boosted Reactions Misclassification

Without the two step approach, a single test may yield a negative result initially but show a positive result upon repeat testing months or years later. This pattern, called the booster phenomenon, could be mistaken for a new infection. The two step test clarifies this by revealing boosted responses early on.

Procedure of the Two Step Mantoux Test

The procedure involves two separate administrations of the tuberculin skin test spaced one to three weeks apart. The process requires precise technique and accurate measurement of skin reactions to ensure reliable results.

Step 1: Initial Mantoux Test

The first step involves injecting 0.1 mL of purified protein derivative (PPD) intradermally on the inner surface of the forearm. After 48 to 72 hours, the injection site is examined and the diameter of induration (not erythema) is measured in millimeters.

Step 2: Second Mantoux Test

If the initial test is negative, a second test is administered 1 to 3 weeks later at a different site on the forearm. This step identifies individuals whose immune response was initially too weak to provoke a significant reaction but who demonstrate a boosted response upon re-exposure.

Measurement and Documentation

Accurate measurement of the induration diameter is essential. The healthcare professional must palpate the area to detect firmness and record the size in millimeters. Documentation should include test dates, injection sites, and induration sizes for both tests.

Interpretation of Results

Interpreting the results of the two step Mantoux test requires understanding the size of induration and the individual's risk factors for tuberculosis infection or disease.

Positive and Negative Reactions

A positive Mantoux test is indicated by an induration above a specific size threshold, which varies based on risk group:

- 5 mm or more in high-risk individuals (e.g., HIV-positive patients, recent contacts of TB cases)
- 10 mm or more in moderate-risk groups (e.g., healthcare workers, recent immigrants from high-prevalence countries)
- 15 mm or more in individuals with no known risk factors

Identification of Boosted Reactions

If the first test is negative and the second test shows a positive reaction, the result is considered a boosted reaction, indicative of past TB exposure or BCG vaccination rather than a new infection. This distinction helps prevent misinterpretation during future screenings.

Implications of Test Results

Positive results usually prompt further evaluation, including chest radiographs and consideration of preventive therapy. Negative results in low-risk individuals generally require no further action but should be interpreted in context.

Factors Affecting Test Accuracy

Several factors can influence the accuracy and reliability of the two step Mantoux test, impacting both false positives and false negatives.

BCG Vaccination

Vaccination with BCG can cause false-positive reactions due to cross-reactivity with the tuberculin antigen. The effect diminishes over time but may complicate interpretation, especially in individuals vaccinated after infancy.

Immunosuppression

Conditions such as HIV infection, malignancy, or immunosuppressive therapy can suppress the immune response, leading to false-negative results. The two step test may help detect boosted responses despite immunosuppression but is not fully reliable in severely immunocompromised individuals.

Technical Factors

Proper administration technique, timing of reading the test, and accurate measurement are critical. Errors in any of these steps can result in inaccurate results.

Recent TB Exposure

Testing too soon after exposure may produce false negatives due to the window period before the immune system reacts. The two step test is not designed to address this but should be interpreted carefully in such contexts.

Advantages and Limitations

The two step Mantoux test offers distinct benefits but also has inherent limitations that must be considered in clinical practice.

Advantages

- Improved detection of latent tuberculosis by identifying boosted reactions
- Reduction in misclassification of new infections versus past exposure
- Cost-effective and widely available screening tool
- Non-invasive and generally safe with minimal adverse effects

Limitations

- Requires two patient visits, which may affect compliance
- Potential for false positives due to BCG vaccination or non-tuberculous mycobacteria
- Reduced sensitivity in immunocompromised patients
- Interpretation variability based on risk factors and exposure history

Alternatives to the Two Step Mantoux Test

Several modern diagnostic tools are available that may complement or replace the two step Mantoux test, particularly in certain clinical settings.

Interferon-Gamma Release Assays (IGRAs)

IGRAs are blood tests that measure the immune response to TB-specific antigens. They offer higher specificity than the Mantoux test, especially in BCG-vaccinated individuals, and require only a single patient visit.

Chest Radiography

Chest X-rays are used to identify active pulmonary tuberculosis but are not effective for detecting latent infection. They are commonly used to complement positive Mantoux test results.

Clinical and Epidemiological Assessment

Risk factor analysis, symptom screening, and exposure history remain essential components of TB diagnosis and should be integrated with test results for accurate interpretation.

Frequently Asked Questions

What is the two-step Mantoux test?

The two-step Mantoux test is a diagnostic method used to detect latent tuberculosis infection. It involves administering two tuberculin skin tests (TST) spaced 1 to 3 weeks apart to differentiate between a boosted reaction and a new infection.

Why is the two-step Mantoux test preferred over a single test in some cases?

The two-step Mantoux test is preferred for individuals undergoing periodic tuberculosis screening because it helps identify a boosted reaction due to past infection or BCG vaccination, reducing the risk of false-negative results on subsequent tests.

How is the two-step Mantoux test performed?

First, a small amount of tuberculin purified protein derivative (PPD) is injected intradermally. After 48 to 72 hours, the test site is examined for induration. If negative, a second test is administered 1 to 3 weeks later to check for a boosted reaction.

What does a positive result in the two-step Mantoux test indicate?

A positive result indicates that the person has been exposed to *Mycobacterium tuberculosis* and may have a latent tuberculosis infection, requiring further evaluation and possibly treatment.

Who should undergo the two-step Mantoux test?

The two-step Mantoux test is recommended for healthcare workers, people with repeated TB exposure risk, and individuals undergoing serial tuberculosis screening to establish an accurate baseline.

What is a boosted reaction in the two-step Mantoux

test?

A boosted reaction occurs when the first test stimulates the immune system, causing a larger reaction on the second test. This indicates a past TB infection or BCG vaccination rather than a new infection.

How long should the interval be between the two steps of the Mantoux test?

The interval between the first and second Mantoux tests is typically 1 to 3 weeks to allow time for the immune system to boost the response if previously sensitized.

Can the two-step Mantoux test differentiate between latent and active TB?

No, the two-step Mantoux test cannot differentiate between latent and active tuberculosis. Additional clinical evaluation and diagnostic tests are required to diagnose active TB.

Are there any limitations to the two-step Mantoux test?

Yes, limitations include false positives due to BCG vaccination or non-tuberculous mycobacteria, false negatives in immunocompromised individuals, and the requirement for two visits to complete the test.
